Monitored Natural Attenuation of Petroleum Hydrocarbons

U.S. EPA REMEDIAL TECHNOLOGY FACT SHEET

Scope of this fact sheet:

This fact sheet explains what "monitored natural attenuation" means when the term is used to describe a potential strategy to remediate a contaminated site. It also describes the various physical, chemical and biological processes of natural attenuation that may occur at a site. This fact sheet is written for an audience with little or no scientific background and is meant to aid Federal, State, and local regulators in educating the public on complex environmental issues. Other informational materials are in preparation and will provide more specific details and scientific depth for the evaluation of monitored natural attenuation as a remedy at specific sites.

What Is Monitored Natural Attenuation?

The term “monitored natural attenuation,” as used by the EPA, refers to the reliance on natural processes to achieve site-specific remedial objectives. Where found to be a viable remedy, monitored natural attenuation may be used within the context of a carefully controlled and monitored site cleanup approach. To be considered an acceptable alternative, monitored natural attenuation would be expected to achieve site remedial objectives within a time frame that is reasonable compared to that offered by other more active methods. Monitored natural attenuation is always used in combination with "source control;" that is, removal of the source of the contamination as far as practicable.

Natural attenuation processes include a variety of physical, chemical, or biological processes that, under favorable conditions, act without human intervention to reduce the mass, toxicity, mobility, volume, or concentration of contaminants in soil or ground water. These processes include biodegradation; dispersion; dilution; sorption; volatilization; and chemical or biological stabilization, transformation, or destruction of contaminants.

Spills and leaks of petroleum hydrocarbons such as gasoline, diesel, motor oils, and similar materials have caused widespread contamination in the environment. Generally these contaminants are present both in NAPL form (non-aqueous phase liquid; the bulk liquid petroleum hydrocarbon) and also as dissolved contaminants in the ground water. Cleanup of both the NAPL and dissolved contamination in soils and ground water using many common remedial techniques is often expensive and slow. However, under the proper conditions at some sites, natural attenuation can contribute significantly to remediation of dissolved petroleum hydrocarbon contamination and may accomplish site remediation goals at a lower cost than conventional remediation technologies, within a similar time frame. Natural attenuation is not expected to remediate NAPL.

How Does Natural Attenuation Work?

Biodegradation

One of the most important components of natural attenuation is biodegradation—the change in form of compounds carried out by living creatures such as microorganisms. Under the right conditions, microorganisms can cause or assist chemical reactions that change the form of the contaminants so that little or no health risk remains. Biodegradation is important because many important components of petroleum hydrocarbon contamination can be destroyed by biodegradation. Biodegrading microorganisms are found almost everywhere, and biodegradation can be very safe and effective.

Many of the most environmentally significant components of petroleum hydrocarbons such as BTEX (benzene, toluene, ethyl benzene, and the xylenes) and some PAHs (polynuclear aromatic hydrocarbons) can be biodegraded under the proper environmental conditions. However, some PAHs, MTBE (methyl tertiary butyl ether, a gasoline additive) and other components of petroleum hydrocarbons may not readily biodegrade. Generally speaking, the petroleum hydrocarbons that are most mobile in the environment (except for MTBE) are also readily biodegraded. Once the more mobile and easily degradable petroleum hydrocarbons are removed, the remaining hydrocarbons, which are not readily degraded, can still pose a high risk in the immediate vicinity of the area in which they remain.

Microorganisms are most effective at degrading low to moderate concentrations of contaminants. High concentrations and very low concentrations of contaminants may not be biodegradable.
Contaminants in the NAPL phase are not effectively degraded by microorganisms.

As contaminants biodegrade, the products of the degradation process may or may not be less harmful than the original contaminants. Therefore, it is important to investigate the site processes carefully to be sure that biodegradation is making the site safer. Fortunately, petroleum hydrocarbons appear to degrade to less harmful products in almost all cases. Also, under some conditions, the microbial activity involved in degrading the contaminants could cause mobilization of certain materials such as manganese or arsenic which could cause environmental problems. Monitoring for these potential problems is necessary.

Sorption

The soil and sediment particles (sand, silt, clay, organic matter) through which the ground water and dissolved contaminants move can sorb the contaminant molecules onto the particle surfaces, and hold bulk liquids in the pores in and between the particles, thereby slowing or stopping the movement of the contaminants. This process can reduce the likelihood that the contaminants will reach a location (such as a drinking water well or stream) where they would directly affect human or environmental health.

 Dispersion and Dilution

As the dissolved contaminants move farther away from the source area, the contaminants are dispersed and diluted to lower and lower concentrations over time. Eventually the contaminant concentrations may be reduced so low that the risk to human and environmental health will be minimal.

**Chemical Reactions**

Some contaminants degrade by chemical reactions (that are not facilitated by microorganisms). However, most petroleum hydrocarbons are not significantly degraded by chemical reactions in soil or ground water.

**Volatilization (Evaporation)**

Many petroleum hydrocarbons evaporate readily into the atmosphere, where air currents disperse the contaminants, reducing the concentration. In some cases, this means of natural attenuation may be useful, since the hydrocarbons can be broken down by sunlight. Vapors in contact with soil microorganisms may be biodegraded. Volatilization from NAPL or ground water into soil gas may be an important exposure pathway in a risk analysis.

**Importance of Natural Attenuation Processes**

The processes involved in natural attenuation are operating at all contaminated sites, but the contribution of natural attenuation to achieving remediation goals varies in different situations. At some sites natural attenuation may meet all the remedial goals, and at other sites natural attenuation may make little or no contribution. Therefore, before natural attenuation can be selected as a remedial
alternative, it is necessary to study each contaminated site carefully
to determine how effective natural attenuation is for attaining site
remediation goals.

Bulk petroleum hydrocarbons—gasoline, diesel, motor oil, etc., in the
NAPL form, rather than dissolved in water or sorbed on soil particles—
are not readily degraded by microorganisms. Also, dispersion,
dilution and sorption of the NAPL is slow. Therefore, it is important
to determine where this NAPL may be at a polluted site, in order to
remove or contain as much of it as possible, because the processes
of natural attenuation would not effectively remediate most of this
material in a reasonable time frame. Natural attenuation processes
are usually of most significance for the remediation of those
contaminants dissolved in water, sorbed on soil particles, or in the
vapor form.

How Is Natural Attenuation Evaluated?

In order to decide what contribution natural attenuation can make to
meeting site remediation goals, very detailed site investigations
must be carried out. Generally, the investment in site characterization
for determining the applicability of natural attenuation is at least as
expensive and time consuming, if not more so, than for any other site
remediation technology. However, the long-term costs for natural
attenuation (if natural attenuation is able to achieve most of the site
remediation goals) may be less than for other remedial technologies.

In order to properly evaluate natural attenuation at a site, it is
necessary to know the location and concentration of the contami-
nants, and how the contaminants move in the environment. Since
contaminants commonly move dissolved in water, the movement of
ground water at the site must be carefully investigated to determine
how the water moves, when it moves and where it moves. The
subsurface is often very complex in terms of water movement
pathways, and determination of these pathways can be expensive.

Also, evaluation of natural attenuation processes may require a
detailed understanding of the site geochemistry, especially where
biodegradation processes are involved. The compounds that may
be associated with microbial activity, such as oxygen, carbon dioxide,
nitrate, sulfate, iron, etc., should be measured in order to gain
understanding of what processes the microorganisms are using,
how fast these processes are occurring, and what the results of these
processes are likely to be.

Evaluation of natural attenuation usually involves not only the
determination of what processes of natural attenuation are occurring,
but also the estimation of what the results of these processes will be
in the future. Therefore, use of natural attenuation as part of the site
remedial plan will necessarily require that a long-term monitoring
plan be instituted. The monitoring plan should provide information
to allow regulators to decide if natural attenuation is meeting site
objectives, and to verify that there are no changes in conditions
affecting natural attenuation. A detection system for early warning
of impacts on sensitive receptors, such as drinking water wells,
streams and wetlands should be provided. Also, plans must be
developed for contingency remedial efforts that can be implemented
if natural attenuation processes do not fulfill expectations.

Summary

Natural attenuation processes occur to varying degrees in all
petroleum hydrocarbon contamination sites, and may contribute
significantly to site remedial goals. Biodegradation processes can be
particularly important for natural attenuation of petroleum
hydrocarbons, because microorganisms can degrade most
environmentally significant petroleum hydrocarbons. Hydrocarbons
dissolved in water or sorbed on soil particles are the most readily
subject to natural attenuation processes, but bulk hydrocarbons
(NAPLs) are not readily subject to natural attenuation in the short
